We consider in this paper systems modeled by timed automata. The timing bounds involved in the action guards and location invariants of our timed automata are not constants, but parameters. Those parametric timed automata allow the modelling of various kinds of timed systems, e.g. communication protocols or asynchronous circuits. We will also assume that we are given an initial tuple $\pi_0$ of values for the parameters, which corresponds to values for which the system is known to behave properly. Our goal is to compute a constraint $K_0$ on the parameters, satisfied by $\pi_0$, guaranteeing that, under any parameter valuation satisfying $K_0$, the system behaves in the same manner: for any two parameter valuations satisfying $K_0$, the behaviors of the timed automata are (time-abstract) equivalent, i.e., the traces of execution viewed as alternating sequences of actions and locations are identical. We present an algorithm $\text{InverseMethod}$ that terminates in the case of acyclic models, and discuss how to extend it to the cyclic case. We also explain how to combine our method with classical synthesis methods which are based on the avoidance of a given set of bad states. A prototype implementation has been done, and various experiments are described.

Keywords: Parameter synthesis; reachability analysis; time-abstract equivalence.

1. Introduction

Timed automata are finite control automata equipped with clocks, which are real-valued variables which increase uniformly. This model is useful for reasoning about real-time systems, because one can specify quantitatively the interval of time during which the transitions can occur, using the bounds involved in invariants and

*This work is partially supported by the Agence Nationale de la Recherche, grant ANR-06-ARFU-005, and by Institut Farman (ENS Cachan).
guards. However, the behavior is very sensitive to the values of these bounds, and it is rather difficult to find their correct values. It is therefore interesting to reason parametrically, by considering that these bounds are unknown constants, or parameters and try to synthesize a constraint on these parameters, in order to ensure a correct behavior. Such automata are called parametric timed automata (PTA).

**Context.** The synthesis of constraints for PTAs (and more generally for the larger class of parametric hybrid automata) has been mainly done by supposing one is given a set of “bad states” (see, e.g., [12]). The goal is to find a set of parameters for which the considered timed (or hybrid) automaton does not reach a given set of bad states. The problem is known to be semi-solvable (if the algorithm terminates the result is correct) by introducing the parameters as state variables and computing the set of reachable states. We call such a method a classical (or “bad-state oriented”) method.

The parameter design problem for parametric hybrid automata was formulated and solved by [14], but the proposed solution is tractable for only very simple systems with few parameters. If a counterexample is found, i.e., if there is a path reaching a bad state, then the current constraint on the parameters is refined in order to make the counterexample infeasible. If all counterexamples have been eliminated, the resulting constraint describes a set of parameters for which the system is safe, in the sense that no path reaches the set of bad states.

In order to increase the efficiency (and the termination) of the method, some approximations are sometimes used for implementing the operator on the constraint that makes the counterexample infeasible (e.g., [12]). This is in the style of CEGAR-based methods (counter-example guided abstraction refinement [9]).

The synthesis of constraints has been implemented in the context of PTAs or hybrid systems, e.g. in [5] using tool TReX [10], or in [15] using an extension of Uppaal [16] for linear parametric model checking. Note that [5] is able to infer non-linear constraints. Another interesting related work on PTA is presented in [15], which gives decidability results for the verification of a special class, called “L/U automata”. Two subclasses of L/U automata, called lower-bound and upper-bound PTA, are also considered in [22], with decidability results. The synthesis of constraints has been studied more specifically in the context of asynchronous circuits, mainly by Myers and co-workers (see, e.g., [24]), and by Clarisó and Cortadella (see, e.g., [8,7]). They also proceed by analyzing failure traces and generating timing constraints that prevent the occurrence of such failures.

**Contribution.** In this paper, we propose an inverse (or “good-state oriented”) method, which does not suppose given a set of bad states that should be avoided, but rather a “good instantiation” $\pi_0$ of the parameters that one wants to generalize. More precisely, we want to generate a constraint $K_0$ on the parameters that corresponds to a set such that, for all instantiation $\pi$ of parameters in this set, the behavior of the timed automaton $A$ is (time-abstract) equivalent to the behavior of $A$ under $\pi_0$, in a sense that will be defined later.
Our procedure consists of generating runs starting from the initial state, and removing states incompatible with the reference values by appropriately refining the current constraint $K_0$ on the parameters. The generation procedure is then restarted until a new incompatible state is produced, and so on, iteratively until no incompatible state is generated.

**Toy example.** Let us consider the parametric timed automaton (PTA) schematized on Fig. 1, following the formalism defined in Sect. 2.2. This PTA contains two clocks $x_1$ and $x_2$, three parameters $p_1$, $p_2$, and $p_3$, and three locations $q_0$, $q_1$, and $q_2$. The initial location $q_0$ has invariant $x_1 \leq p_1$. The transition from $q_0$ to $q_1$, labelled $a$, has guard $x_2 \geq p_2$, and resets $x_1$. The transition from $q_0$ to $q_2$, labelled $b$, has guard $x_1 \geq p_3$, and does not reset any clock. Let us assume that $q_2$ corresponds to a “bad location”. Classical methods, using this information, will generate the constraint $Z : p_1 < p_3$, which guarantees that the location is not reachable. Suppose now that we are given the following “good” instantiation of the parameters $\pi_0 : p_1 = 4 \land p_2 = 2 \land p_3 = 6$, under which the PTA is assumed to have a “good” behavior. Then our inverse method will generate the constraint $K_0 : p_1 < p_3 \land p_2 \leq p_1$. For all instantiation $\pi$ of the parameters satisfying $K_0$, our method guarantees that the PTA behaves in the same manner as under $\pi_0$. We are thus ensured that the behavior of the PTA is correct. Note that $K_0$ is strictly smaller than $Z$. On the one hand, this may be viewed as a limitation of our method. On the other hand, this may indicate that there are incorrect behaviors other than those corresponding to the reaching of $q_2$. For example, there are some parameter instantiations satisfying $Z$, under which a deadlock of the PTA occurs at the initial location $q_0$. In contrast, our inverse method guarantees that such a deadlock is impossible under any instance satisfying $K_0$ (because the deadlock does not occur under $\pi_0$).

**Overview of the paper.** We first introduce the notion of Parametric Timed Automata in Sect. 2. We then present our method of synthesis of constraints in Sect. 3, and show its correctness. We present in Sect. 4 a variant of the method in order to improve termination. We describe some experiments in Sect. 5. We present in Sect. 6 an extension allowing to enlarge the synthesized constraint by exploiting some additional information. We give some final remarks in Sect. 7.

2. Parametric Timed Automata
These preliminary definitions are mainly borrowed from [15].
2.1. Constraints on the Clocks and the Parameters

Throughout this paper, we assume a fixed set \( X = \{x_1, \ldots, x_H\} \) of clock variables. A clock variable is a variable \( x_i \) with value in \( \mathbb{R}_+ \), where \( \mathbb{R}_+ \) is the standard notation for the set of real numbers greater or equal to 0. All clocks evolve linearly at the same rate. We define a clock valuation as a function \( w : X \to \mathbb{R}_+ \) assigning a nonnegative real value to each clock variable. We will often identify a valuation \( w \) with the point \((w(x_1), \ldots, w(x_H))\). Given a constant \( d \in \mathbb{R}_+ \), we use \( w + d \) to denote \((w(x_1) + d, \ldots, w(x_H) + d)\).

Throughout this paper, we assume a fixed set \( P = \{p_1, \ldots, p_M\} \) of parameters. A parameter valuation \( \pi \) is a function \( \pi : P \to \mathbb{R}_+ \) assigning a nonnegative real value to each parameter. There is a one-to-one correspondence between valuations and points in \((\mathbb{R}_+)^M\). We will often identify a valuation \( \pi \) with the point \((\pi(p_1), \ldots, \pi(p_M))\).

**Definition 1.** A linear inequality on the parameters \( P \) (resp. linear inequality on the clock variables \( X \) and the parameters \( P \)) is an inequality \( e \prec e' \), where \( \prec \in \{<, \leq\} \), and \( e, e' \) are two linear terms of the form

\[
\Sigma_i \alpha_i p_i + d, \quad (\text{resp. } \Sigma_i \alpha_i p_i + \Sigma_j \beta_j x_j + d)
\]

where \( 1 \leq i \leq M, 1 \leq j \leq H \) and \( \alpha_i, \beta_j, d \in \mathbb{N} \). A (convex) constraint on the parameters \( P \) (resp. (convex) constraint on the clock variables \( X \) and the parameters \( P \)) is a conjunction of inequalities on \( P \) (resp. on \( X \) and \( P \)).

In the sequel, \( J \) will denote a linear inequality on the parameters, and the letter \( K \) (resp. \( C \)) will denote a constraint on the parameters (resp. on the clocks and the parameters). The negation of a linear inequality \( J \) of the form \( e < e' \) (resp. \( e \leq e' \)) is the linear inequality \( e' \leq e \) (resp. \( e' < e \)), and will be denoted by \( \neg J \).

Given a parameter valuation \( \pi \) and a constraint \( C, C[\pi] \) denotes the constraint obtained by replacing each parameter \( p \) in \( C \) with \( \pi(p) \). Likewise, given a clock valuation \( w, C[\pi][w] \) denotes the expression obtained by replacing each clock variable \( x \) in \( C[\pi] \) with \( w(x) \). A clock valuation \( w \) satisfies constraint \( C[\pi] \) (denoted by \( w \models C[\pi] \)) if \( C[\pi][w] \) evaluates to true. We say that a parameter valuation \( \pi \) satisfies a constraint \( C \), denoted by \( \pi \models C \), if the set of clock valuations that satisfy \( C[\pi] \) is nonempty. We use the notation \( <w, \pi> \models C \) to indicate that \( C[\pi][w] \) evaluates to true. We say that \( C \subseteq D \) if \( \forall w, \pi : <w, \pi> \models C \Rightarrow <w, \pi> \models D \). We say that \( C = D \) if \( C \subseteq D \) and \( D \subseteq C \).

Given a constraint \( C \), it is sometimes convenient to rename the set of variables \( X = \{x_1, \ldots, x_H\} \) as \( X' = \{x'_1, \ldots, x'_H\} \). We use the notation \( C(X) \) (resp. \( C(X') \)) to indicate that \( X \) (resp. \( X' \)) is the set of clock variables occurring in \( C \).

Similarly to the semantics of constraints on the clocks and the parameters, we say that a parameter valuation \( \pi \) satisfies a constraint \( K \) on the parameters, denoted by \( \pi \models K \), if the expression obtained by replacing each parameter \( p \) in \( K \) with \( \pi(p) \) evaluates to true. We will consider \( \text{True} \) as a constraint on the parameters, corresponding to the set of all possible values for \( P \).

Given a constraint \( C \) on the clocks and the parameters, we denote by \( \exists X : C \)
the constraint on the parameters obtained from $C$ after elimination of the clock variables, i.e., \( \{ \pi \mid \exists w : <w, \pi> \models C \} \).

### 2.2. Parametric Timed Automata

We assume familiarity with timed automata (see, e.g., [1, 18]), which are an extension of the class of standard automata. All clock constraints of standard timed automata are boolean combinations of atomic conditions that compare values with natural numbered constants. With respect to the classical definition, this class is contrived by the fact that guards and invariants are necessarily in conjunctive form, but this is not restrictive in practice. The following definition is an extension of the class of timed automata to the parametric case. Parametric timed automata allow within guards and invariants the use of parameters in place of constants (see [2]).

**Definition 2.** Given a set of clocks $X$ and a set of parameters $P$, a parametric timed automaton (PTA) $A$ is a 6-tuple of the form $A = (\Sigma, Q, q_0, K, I, \rightarrow)$, where $\Sigma$ is a finite set of actions, $Q$ is a finite set of locations, $q_0 \in Q$ is the initial location, $K$ is a constraint on the parameters $P$, $I$ is the invariant, assigning to every $q \in Q$ a constraint $I_q$ on the clocks and the parameters, and $\rightarrow$ is a step relation consisting of elements of the form $(q, g, a, \rho, q')$ (also denoted by $q \xrightarrow{g,a,\rho} q'$) where $q, q' \in Q$, $a \in \Sigma$, $\rho \subseteq X$ is a set of clock variables to be reset by the step, and $g$ (the step guard) is a constraint on the clocks and the parameters.

In the sequel, we consider the PTA $A = (\Sigma, Q, q_0, K, I, \rightarrow)$. We simply denote this PTA by $A(K)$, in order to emphasize the fact that only $K$ will change in $A$.

We use $X' = \rho(X)$, where $X'$ is a renaming of $X$, to denote the conjunction of equalities $x'_i = 0$ for all $x_i \in \rho$, and $x'_i = x_i$ for all the other variables $x_i$ of $X$.

For every parameter valuation $\pi = (\pi_1, \ldots, \pi_M)$, $A[\pi]$ denotes the PTA $A(K)$, where $K$ is $\bigwedge_{i=1}^M p_i = \pi_i$. This corresponds to the PTA obtained from $A$ by substituting every occurrence of a parameter $p_i$ by $\pi_i$ in the guards and invariants. Note that $A[\pi]$ is a standard timed automaton. (Strictly speaking, $A[\pi]$ is only a timed automaton if $\pi$ assigns an integer to each parameter.) In the sequel, we suppose that one is given a valuation $\pi$ of the parameters, and the PTA $A[\pi]$.

**Definition 3.** A labeled transition system (LTS) over a set of symbols $\Sigma$ is a triple $\mathcal{L} = (S, S_0, \Rightarrow)$, with $S$ a set of states, $S_0 \subseteq S$ a set of initial states, and $\Rightarrow \subseteq S \times \Sigma \times S$ a transition relation. We write $s \xrightarrow{a} s'$ for $(s, a, s') \in \Rightarrow$. A run (of length $m$) of $\mathcal{L}$ is a finite alternating sequence of states $s_i \in S$ and symbols $a_i \in \Sigma$ of the form $s_0 \xrightarrow{a_1} s_1 \xrightarrow{a_2} \ldots \xrightarrow{a_{m-1}} s_m$, where $s_0 \in S_0$. A state $s_m$ is reachable if it is the last state of some run $R$. We say that $R$ reaches $s_m$.

**Definition 4.** The concrete semantics of $A[\pi]$ is the LTS $(S, S_0, \Rightarrow)$ over $\Sigma$ where $S = \{ (q, w) \in Q \times (X \rightarrow \mathbb{R}_+) \mid <w, \pi> \models I_q \}$, $S_0 = \{ (q_0, w) \mid <w, \pi> \models I_{q_0} \land w = (w_0, \ldots, w_0) \text{ for some } w_0 \}$.
and the transition predicate \( \Rightarrow \) is specified by the following three rules. For all \((q, w), (q', w') \in S, d \geq 0 \) and \( a \in \Sigma, \)
- \((q, w) \xrightarrow{a} (q', w') \) if \( \exists g, \rho: q \xrightarrow{g, a, \rho} q' \) and \( <w, \pi> \models g \land w' = \rho(w); \)
- \((q, w) \xrightarrow{d} (q', w') \) if \( q' = q \) and \( w' = w + d; \)
- \((q, w) \xrightarrow{\Rightarrow} (q', w') \) if \( \exists d, w'' : (q, w) \xrightarrow{\Rightarrow} (q', w'') \xrightarrow{d} (q', w'). \)

We consider with the definition of \( S_0 \) that all clocks are initially set to 0, or have evolved linearly in the bounds given by \( I_0. \) A state (resp. run) in the concrete semantics will be referred to as a concrete state (resp. concrete run). We now define a trace as a time-abstract run, i.e., an alternating sequence of locations and actions.

**Definition 5.** Given a PTA \( A \) and a concrete run \( R \) of \( A[\pi] \) of the form \((q_0, w_0) \xrightarrow{a_0} \cdots \xrightarrow{a_{m-1}} (q_m, w_m)\), the trace associated to \( R \) is the alternating sequence of locations and actions \( q_0 \xrightarrow{a_0} \cdots \xrightarrow{a_{m-1}} q_m. \) The traces of \( A[\pi] \) refer to the set of traces associated to the runs of \( A[\pi]. \)

### 2.3. Network of Parametric Timed Automata

We now introduce the notion of network of parametric timed automata.

**Definition 6.** For all \( 1 \leq i \leq N, \) let \( A_i = (\Sigma_i, Q_i, (q_0)_i, K_i, I_i, \rightarrow_i) \) be a PTA on a set of clocks \( X_i \) and a set of parameters \( P_i. \) The sets \( Q_i, P_i, \) and \( X_i \) are mutually disjoint. A network of parametric timed automata (NPTA) is \( A = A_1 || \cdots || A_N, \) where \( || \) is the standard operator for parallel composition.

This NPTA \( A \) is a PTA \((\Sigma, Q, q_0, K, I, \rightarrow)\) over \( X \) and \( P, \) where \( X = \bigcup_{i=1}^{N} X_i, P = \bigcup_{i=1}^{N} P_i, \Sigma = \bigcup_{i=1}^{N} \Sigma_i, Q = \prod_{i=1}^{N} Q_i, \) \( q_0 = \langle (q_0)_1, \ldots, (q_0)_N \rangle, \) \( K = \bigwedge_{i=1}^{N} K_i, \) \( I_{(q_1, \ldots, q_N)} = \bigwedge_{i=1}^{N} (I_i)_q, \) for all \( \langle q_1, \ldots, q_N \rangle \in Q, \) and \( \rightarrow \) is defined as follows. For all \( a \in \Sigma, \) let \( T_a \) be the subset of indices \( i \in 1, \ldots, N \) such that \( a \in \Sigma_i. \) For all \( a \in \Sigma, \) for all \( \langle q_1, \ldots, q_N \rangle \in Q, \) for all \( \langle q'_1, \ldots, q'_N \rangle \in Q, \) \((\langle q_1, \ldots, q_N \rangle, g, a, \rho, \langle q'_1, \ldots, q'_N \rangle) \in \rightarrow \) if, for all \( i \in T_a, \) there exist \( g_i, \rho_i \) s.t. \((q_i, g_i, a, \rho_i, q'_i) \in \rightarrow_i, g = \bigwedge_{i \in T_a} g_i, \rho = \bigcup_{i \in T_a} \rho_i, \) and, for all \( i \notin T_a, q'_i = q_i. \)

### 2.4. The Inverse Problem

In this paper, starting from an instantiation \( \pi_0 \) of the set \( P \) of parameters, we are interested in finding a constraint \( K_0 \) on the parameters, such that, for any valuation \( \pi \) of \( P \) satisfying \( K_0, \) the behaviors (in terms of sets of traces) of \( A[\pi] \) and \( A[\pi_0] \) will be the same. Formally, the inverse problem is stated as follows:

Consider a PTA \( A \) and a valuation \( \pi_0 \) of the parameters. Find a constraint \( K_0 \) such that \( \pi_0 \models K_0 \) and, for all \( \pi \models K_0, \) the set of traces of \( A[\pi_0] \) and the set of traces of \( A[\pi] \) are equal.

**Example 7.** Consider an asynchronous “D flip-flop” circuit described in [8] and depicted on Fig. 2. It is composed of 4 gates \((G_1, G_2, G_3 \text{ and } G_4)\) interconnected in
An Inverse Method for Parametric Timed Automata

Fig. 2. Flip-flop circuit.

q₀ → q₁ → q₂ → q₃ → q₄ → q₅ → q₆ → q₇ → q₈

Fig. 3. Graph of traces of the flip-flop circuit under π₀.

...
For each valuation \( \pi \) of the parameters \( P \), we may view a symbolic state \( s \) as the set of pairs \( (q, w) \) where \( w \) is a clock valuation such that \( \langle w, \pi \rangle \models C \).

We say that a state \( s_1 = (q_1, C_1) \) is included in a state \( s_2 = (q_2, C_2) \), denoted by \( s_1 \subseteq s_2 \), if \( q_1 = q_2 \) and \( C_1 \subseteq C_2 \). We say that two states \( s_1 = (q_1, C_1) \) and \( s_2 = (q_2, C_2) \) are equal, denoted by \( s_1 = s_2 \), if \( q_1 = q_2 \) and \( C_1 = C_2 \).

The initial state of \( \mathcal{A}(K) \) is a symbolic state \( s_0 \) of the form \( (q_0, C_0) \), where \( C_0 = K \land I_{q_0} \land \bigwedge_{i=1}^{H-1} x_i = x_{i+1} \). \( K \) is the initial constraint, \( I_{q_0} \) is the invariant of the initial state, and the rest of the expression lets clocks evolve from the same initial value.

The symbolic semantics of a PTA is given in the following. Given a symbolic state \( s = (q, C) \), a symbolic step of the automaton from \( s \) is defined below. Given a constant \( d \in \mathbb{R}_+ \), we use \( X + d \) to denote the set \( \{x_1 + d, \ldots, x_H + d\} \).

- \( (q, C) \xrightarrow{a} (q', C') \) if \( (q, g, a, \rho, q') \in \rightarrow \), and \( C' \) is a constraint on the clocks and parameters defined, using the set of (renamed) clock variables \( X' \), by:
  \[
  C'(X') = (\exists X : (C(X) \land g(X) \land X' = \rho(X) \land I_q(X'))) .
  \]
- \( (q, C) \xrightarrow{d} (q', C') \), where \( d \) is a new parameter with values in \( \mathbb{R}_+ \), which means that \( C' \) is given by:
  \[
  C'(X') = (\exists X : (C(X) \land X' = X + d \land I_q(X'))) .
  \]
- \( (q, C) \xrightarrow{a} (q', C') \) if \( \exists C'' \) such that \( (q, C) \xrightarrow{a} (q', C'') \) and \( (q', C'') \xrightarrow{d} (q', C') \), i.e., \( C' \) is a constraint on the clocks and the parameters obtained by removing \( X \) and \( d \) from the following expression:\
  \[
  C'(X') = (\exists X, d : (C(X) \land g(X) \land X' = \rho(X) \land I_q(X') \land I_q(X' + d))).
  \]

It can be shown that \( C' \) can be put under the form of a (convex) constraint on the clocks and the parameters, using, e.g., Fourier-Motzkin elimination (see [19]) of \( X \) and \( d \).

**Definition 9.** A symbolic run of \( \mathcal{A}(K) \) (of length \( m \)) is a finite alternating sequence of symbolic states and actions of the form \( s_0 \xrightarrow{a_0} s_1 \xrightarrow{a_1} \cdots \xrightarrow{a_{m-1}} s_m \), such that for all \( i = 0, \ldots, m-1 \), \( a_i \in \Sigma \) and \( s_i \xrightarrow{a_i} s_{i+1} \) is a symbolic step of \( \mathcal{A}(K) \).

**Example 10.** Consider again the PTA \( \mathcal{A}(\text{True}) \) described on Fig. 1. Starting from \( q_0 \), we consider an \( a \)-transition. Thus, we have \( (q_0, C_0) \xrightarrow{a} (q_1, C_1) \). We have \( C_0 : x_1 \leq p_1 \land x_1 = x_2 \). By eliminating \( X \) and \( d \) in \( \exists X, d : x_1 \leq p_1 \land x_1 = x_2 \land x_2 \geq p_2 \land x'_1 = 0 \land x'_2 = x_2 \), and renaming \( X' \) back to \( X \), we get \( C_1 : x_1 = 0 \land x_2 \leq p_1 \land x_2 \geq p_2 \).

One defines \( \text{Post}^i_{\mathcal{A}(K)}(S) \) as the set of states reachable from \( S \) in exactly \( i \) steps, and \( \text{Post}^{*\mathcal{A}(K)}(S) \) as the set of all states reachable from \( S \) in \( \mathcal{A}(K) \) (i.e., \( \text{Post}^{*\mathcal{A}(K)}(S) = \bigcup_{i \geq 0} \text{Post}^i_{\mathcal{A}(K)}(S) \)). In the sequel, we will be interested in computing the set \( \text{Post}^{*\mathcal{A}(K)}(\{s_0\}) \), where \( s_0 \) is the initial state of \( \mathcal{A}(K) \). Note that if

\(^{a}\)In \( C'(X') \), we use the expression \( I_{q'}(X') \land I_{q'}(X' + d) \) instead of \( \forall 0 \leq e \leq d : I_{q'}(X' + e) \), using the fact that \( I_{q'} \) is convex.
Post^i+1_{A(K)}(\{s_0\}) = \emptyset$ (or, more generally, if $Post^i_{A(K)}(\{s_0\}) \subseteq \bigcup_{j=0}^i Post^j_{A(K)}(\{s_0\})$), then $Post^*_{A(K)}(\{s_0\}) = \bigcup_{j=0}^i Post^j_{A(K)}(\{s_0\})$.

We now define the notion of trace associated to a symbolic run.

**Definition 11.** Given a PTA $A$ and a symbolic run $R$ of the form $(q_0,C_0) \xrightarrow{a_0} \cdots \xrightarrow{a_{m-1}} (q_m,C_m)$, the trace associated to $R$ is the alternating sequence of locations and actions $q_0 \xrightarrow{a_0} \cdots \xrightarrow{a_{m-1}} q_m$.

We define below the classical notion of time-abstract equivalence between any two runs (see, e.g., [1,21,18]).

**Definition 12.** Let $R_1$ (resp. $R_2$) be a concrete run of $A[\pi]$ or a symbolic run of $A(K)$. $R_1$ and $R_2$ are time-abstract equivalent (or more simply equivalent) if the trace associated to $R_1$ is identical to the trace associated to $R_2$. Similarly, let $\mathcal{R}_1$ (resp. $\mathcal{R}_2$) be a set of concrete runs of $A[\pi]$ or a set of symbolic runs of $A(K)$. $\mathcal{R}_1$ and $\mathcal{R}_2$ are equivalent if any run of $\mathcal{R}_1$ is equivalent to a run in $\mathcal{R}_2$, and conversely.

### 3.2. The Algorithm $\text{InverseMethod}$

Our algorithm makes use of the following notion of incompatible state.

**Definition 13.** Given a valuation $\pi_0$ of the parameters, a symbolic state $(q,C)$ is said to be compatible with respect to $\pi_0$ (or more simply $\pi_0$-compatible) if $\pi_0 \models \exists X : C$, i.e., if $\exists w : <w,\pi_0> \models C$. A state is said to be $\pi_0$-incompatible if it is not $\pi_0$-compatible. We say that a set of states is $\pi_0$-compatible if all its elements are $\pi_0$-compatible.

The test of $\pi_0$-compatibility of a state $(q,C)$ is done by eliminating the clock variables from $\exists X : C$ (e.g., using Fourier-Motzkin algorithm).

We now present the algorithm $\text{InverseMethod}$ in Fig. 4. The inner DO loop removes all the $\pi_0$-incompatible states. The outer DO loop computes the set of all reachable states, and returns the intersection $K_0$ of all the constraints on the parameters associated to the states of $S$. Note that there are two possible sources of nondeterminism in the algorithm: (1) when one selects a $\pi_0$-incompatible state $(q,C)$ (i.e, $\pi_0 \not\models \exists X : C$), and (2) when one selects an inequality $J$ among the conjunction of inequalities $\exists X : C$, that is “responsible” for this $\pi_0$-incompatibility (i.e., such that $\pi_0 \not\models J$, hence $\pi_0 \models \neg J$).

**Remark.** At the last iteration of $\text{InverseMethod}$, we have: $S = Post^*_{A(K)}(\{s_0\})$.

**Example 14.** Let us apply $\text{InverseMethod}$ on our example of PTA depicted on Fig. 1, with $\pi_0 = \{p_1 = 4 \land p_2 = 2 \land p_3 = 6\}$. We start with $K = \text{True}$ and $S = \{(q_0,C_0)\}$ where $C_0$ is $x_1 \leq p_1$ and $x_1 = x_2$. We test whether $S$ is $\pi_0$-compatible: we compute $\exists X : C_0$, which gives the trivially $\pi_0$-compatible constraint $\text{True}$. Thus, $S$ contains no $\pi_0$-incompatible state, and we compute $Post_{A(K)}(S)$. We now have $S = \{(q_0,C_0),(q_1,C_1),(q_2,C_2)\}$ with $C_1 : x_1 = 0 \land x_2 \leq p_1 \land x_2 \geq p_2$ and $C_2 :$
ALGORITHM InverseMethod($A$, $\pi_0$)

Input $A$ : PTA
$\pi_0$ : Reference valuation of $P$

Output $K_0$ : Constraint on the parameters

Variables $i$ : Current iteration
$S$ : Current set of reachable states ($S = \bigcup_{j=0}^{i} \text{Post}^j_{A(K)}(\{s_0\})$)
$K$ : Current constraint on the parameters

$i := 0$; $K := \text{True}$; $S := \{s_0\}$

DO

DO UNTIL $S$ is $\pi_0$-compatible

Select a $\pi_0$-incompatible state $(q, C)$ of $S$
Select an inequality $J$ of ($\exists X : C$) such that $\pi_0 \models \neg J$

$K := K \land \neg J$ ; $S := \bigcup_{j=0}^{i} \text{Post}^j_{A(K)}(\{s_0\})$

OD

IF $\text{Post}_{A(K)}(S) = \emptyset$ THEN RETURN $K_0 := \bigcap_{(q,C) \in S} (\exists X : C)$

$i := i + 1$

$S := S \cup \text{Post}_{A(K)}(S)$

OD

$X_1 = x_2 \land x_1 \leq p_1 \land x_1 \geq p_3$. We test whether $S$ is $\pi_0$-compatible: we compute $\exists X : C_1$, which gives the $\pi_0$-compatible constraint $p_2 \leq p_1$. We compute $\exists X : C_2$, and get $p_3 \leq p_1$, which is $\pi_0$-incompatible. Hence $K = p_1 < p_3$. We perform $S := \bigcup_{j=0}^{i} \text{Post}^j_{A(K)}(\{(q_0, C_0)\})$ with $i = 1$, which gives $S = \{(q_0, C'_0), (q_1, C'_1)\}$, with $C'_0 : x_1 \leq p_1 \land x_1 = x_2 \land p_1 < p_3$ and $C'_1 : x_1 = 0 \land x_2 \leq p_1 \land x_2 \geq p_2 \land p_1 < p_3$.

We test whether $S$ is $\pi_0$-compatible: we compute $\exists X : C'_0$, which gives the $\pi_0$-compatible constraint $p_1 < p_3$; we compute $\exists X : C'_1$, which gives the $\pi_0$-compatible constraint $p_2 \leq p_1 \land p_1 < p_3$. As we have no $\pi_0$-incompatible state, we perform $S := \text{Post}_{A(K)}(S)$, which gives the empty set. The algorithm thus terminates returning $K_0 = (\exists X : C'_0) \land (\exists X : C'_1)$, i.e.: $p_2 \leq p_1 \land p_1 < p_3$.

3.3. Correctness

We now formally establish the correctness of Algorithm InverseMethod.

We suppose in this subsection that InverseMethod($A$, $\pi_0$) terminates with output $K_0$. Let $K$ (resp. $S$) be the current set of reachable states (resp. the current constraint on the parameters) when the algorithm terminates. We have $S = \text{Post}^*_{A(K)}(\{s_0\})$ and $K_0 = \bigcap_{(q,C) \in S} (\exists X : C)$.

Proposition 15. We have $K_0 \subseteq K$.

Proof. From the semantics of PTA, for all state $(q, C) \in S$, we have $(\exists X : C) \subseteq K$, since $S = \text{Post}^*_{A(K)}(\{s_0\})$. As $K_0 = \bigcap_{(q,C) \in S} (\exists X : C)$, then $K_0 \subseteq K$. \hfill \box
Proposition 16. Given $\pi_0$, let $K_0 = \text{InverseMethod}(A, \pi_0)$. We have: $\pi_0 \models K_0$.

Proof. When Algorithm \text{InverseMethod} terminates, the set $S$ is $\pi_0$-compatible (i.e., $\pi_0 \models (\exists X : C)$, for all $(q, C) \in S$). Thus, the intersection $K_0$ of the constraints associated to the states of $S$, i.e., $\bigcap_{(q, C) \in S}(\exists X : C)$, is satisfied by $\pi_0$. \hfill \Box

Let us now show that the set of traces in the concrete semantics and the set of traces in the symbolic semantics are equal. This will lead to Theorem 22, stating the correctness of Algorithm \text{InverseMethod}. First of all, we state that, for each symbolic run of $A(K)$, we can find an equivalent concrete run of $A[\pi]$.

Proposition 17. For all $\pi$ be such that $\pi \models K_0$, for all symbolic run of $A(K)$ reaching $(q, C)$, there exists a clock valuation $w$ such that $<w, \pi> \models C$.

Proof. For all symbolic run of $A(K)$ reaching $(q, C)$, we have $(q, C) \in S$ since $S = \text{Post}^*_A(K)((s_0))$. Moreover, we have $K_0 = \bigcap_{(q, C) \in S}(\exists X : C)$. Thus, for all $\pi \models K_0$, for all $(q, C) \in S$, we have $\pi \models (\exists X : C)$. Hence, there exists a clock valuation $w$ such that $<w, \pi> \models C$. \hfill \Box

Proposition 18. For all symbolic run of $A(K)$ reaching $(q, C)$, for all parameter valuation $\pi$ and clock valuation $w$ such that $<w, \pi> \models C$, there exists an equivalent concrete run of $A[\pi]$ reaching $(q, w)$.

Proof. The proof of Proposition 3.17 in [15] can be adapted in a straightforward manner. \hfill \Box

Proposition 19. For all $\pi \models K_0$, for all symbolic run of $A(K)$, there exists an equivalent concrete run of $A[\pi]$.

Proof. From Prop. 17 and Prop. 18. \hfill \Box

Conversely, we now state that, for each concrete run of $A[\pi]$, we can find an equivalent symbolic run of $A(K)$.

Proposition 20. For all $\pi \models K_0$, for all concrete run of $A[\pi]$, there exists an equivalent symbolic run of $A(K)$.

Proof. The proof of Prop. 3.18 in [15] can be adapted in a straightforward manner to show that, for all $\pi \models K$, for all concrete run of $A[\pi]$, there exists an equivalent symbolic run of $A(K)$. The result follows from the fact that $\pi \models K_0$ implies $\pi \models K$ (by Prop. 15). \hfill \Box

Proposition 21. For all $\pi \models K_0$, the sets of runs of $A(K)$ and $A[\pi]$ are equivalent, i.e., the sets of traces are equal.
Proof. From Prop. 19 and 20.

The following theorem states that $\text{InverseMethod}$ solves our inverse problem as defined in Sect. 2.4.

**Theorem 22.** Suppose that $\text{InverseMethod}(A, \pi_0)$ terminates with output $K_0$. Then, we have: (1) $\pi_0 \models K_0$, and (2) for all $\pi \models K_0$, the sets of concrete runs of $A[\pi_0]$ and $A[\pi]$ are equivalent, i.e., the sets of traces are equal.

Proof. From Prop. 16 and Prop. 21.

### 3.4. Termination

Reachability analysis is known to be undecidable in the framework of PTAs [2, 11], and computations performed with tools on PTAs (such as HyTech [13]) do not always terminate. However, we give a sufficient condition for ensuring termination of our method.

**Proposition 23.** Let $A$ be a PTA and $\pi_0$ be a valuation of $P$. If there exists $n \in \mathbb{N}$ s.t. $Post^i_{A[\pi_0]}(\{s_0\}) = \emptyset$, then algorithm $\text{InverseMethod}$ terminates.

Proof. Let us first consider the inner $DO$ loop for a given $i$. At each iteration, we select a state $s = (q, C)$ of $Post^i_{A(K)}(\{s_0\})$. We select an inequality $J$ in $\exists X : C$, negate $J$, and add it to $K$. Hence, $s$ does not belong to $Post^i_{A(K \land \neg J)}(\{s_0\})$. The traces of $A(K)$ of length $j \leq i$ can be organized under the form a finite tree, say $T$. Likewise, the traces of $A(K \land \neg J)$ of length $j \leq i$ can be organized under the form a finite tree, say $T'$. It is easy to show that $T'$ is a subtree of $T$, i.e., each branch starting from the root of $T'$ is a (sub)branch starting from the (same) root in $T$. Thus no new state can be reached in $A(K \land \neg J)$. Moreover, the branch of $T$ reaching the location corresponding to $s$ does not belong to $T'$. So, the number of nodes of $T'$ is less than the number of nodes of $T$. Hence, the number of states of $Post^i_{A(K \land \neg J)}(\{s_0\})$ is less than the number of states of $Post^i_{A(K)}(\{s_0\})$. Thus, the inner $DO$ loop terminates.

Let us now consider the outer $DO$ loop. Since $Post^i_{A[\pi_0]}(\{s_0\}) = \emptyset$, the symbolic runs of $A[\pi_0]$ have at most length $n - 1$. Let us show by *reductio ad absurdum* that the outer $DO$ loop terminates at iteration $i = n - 1$. Suppose that we are still in the outer $DO$ loop at $i = n$. Thus, there exists a symbolic run of $A(K)$ of length $n$ of the form $(q_0, C_0) \overset{a_0}{\Rightarrow} \cdots \overset{a_{n-1}}{\Rightarrow} (q_{n-1}, C_{n-1}) \overset{a_n}{\Rightarrow} (q_n, C_n)$. Moreover, since all the states in $S = Post^i_{A(K)}(\{s_0\})$ are $\pi_0$-compatible, we have $\pi_0 \models C_i$, for $0 \leq i \leq n$. Hence, there exists $w$ s.t. $\langle w, \pi_0 \rangle \models C_n$. Therefore, by Prop. 18, there exists an equivalent concrete run of length $n$ of $A[\pi_0]$ reaching $(q_n, w)$. It follows from Prop. 3.18 of [15] that there exists an equivalent symbolic run of length $n$ of $A[\pi_0]$, which contradicts the assumption $Post^i_{A[\pi_0]}(\{s_0\}) = \emptyset$. 

\[\square\]
A sufficient condition so that there exists \( n \in \mathbb{N} \) s.t. \( Post^n_{\mathcal{A}[\pi_0]}(\{s_0\}) = \emptyset \) is that the oriented graph depicting the traces associated the symbolic runs of \( \mathcal{A}[\pi_0] \) is acyclic, i.e., traces never pass twice by the same location. This is for example the case of the traces depicted on Fig. 3. A sufficient condition for the acyclicity of the graph of traces is that the oriented graph depicting the PTA \( \mathcal{A} \) be itself acyclic. This is generally the case for synchronous circuits analyzed over a fixed number (typically, 1 or 2) of clock cycles.

### 3.5. Application to the Flip-flop Example

Let us apply our algorithm \textit{InverseMethod} (implemented in the program \textsc{Imitator}, see Sect. 5) to the NPTA modeling the flip-flop circuit and to the instantiation \( \pi_0 \) given in Sect. 2.4. The program generates the following constraint \( K_0^b \):

\[
T_{\text{setup}} < T_{\text{LO}} \quad \land \quad \delta_3^- + \delta_4^+ < T_{\text{HI}} \quad \land \quad \delta_1^- < T_{\text{setup}} \quad \land \quad \delta_1^- > 0 \\
\land \quad T_{\text{hold}} \leq \delta_3^- + \delta_4^+ \quad \land \quad \delta_3^- + \delta_4^- \leq T_{\text{hold}} \quad \land \quad \delta_3^- < T_{\text{hold}}
\]

Besides, by construction on the environment, recall that we have the implicit additional constraint: \( T_{\text{hold}} \leq T_{\text{HI}} \). As formally stated in Theorem 22, one can check that the set of traces coincides with the one depicted on Fig. 3.

In [8], the following constraint \( Z \) is generated in order to prevent bad system behaviors (the bad state is defined as the case where \( CK \downarrow \) occurs before \( Q \uparrow \)):

\[
T_{\text{setup}} > \delta_1^+ + \delta_2^- - \delta_2^- \quad \land \quad T_{\text{hold}} > \delta_1^+ + \delta_3^- \quad \land \quad T_{\text{HI}} > \delta_3^+ + \delta_4^- \quad \land \quad T_{\text{LO}} > T_{\text{setup}} \quad \land \quad \delta_1^- > \delta_2^+
\]

Note that, as we have \( \pi_0 \models Z \), the set of traces under \( \pi_0 \) (and by construction under \( K_0 \)) also prevents bad system behaviors\(^c\). It is easy to check that \( K_0 \) is \textit{uncomparable} with \( Z \), i.e., we can find instantiations satisfying \( K_0 \) and not \( Z \), and vice versa. This suggests to extend \( K_0 \) by applying \textit{InverseMethod} to a new instantiation \( \pi_1 \) such that \( \pi_1 \models Z \) and \( \pi_1 \not\models K_0 \). This will be the subject of Sect. 6.

### 4. Extension to the Cyclic Case

We have seen in Section 3.4 that the algorithm \textit{InverseMethod} terminates in the “acyclic” case. The algorithm does not terminate in the cyclic case in general. We first present a slightly modified version of our algorithm, which terminates in some special cases of the cyclic class while still preserving Theorem 22. Then we present a further extension which terminates more often for cyclic cases, at the price of weakening the equivalence result of Theorem 22.

#### 4.1. First Extension

We state here that a generalization of Algorithm \textit{InverseMethod} is also correct. One slightly modifies the algorithm by replacing the test \( \text{IF} \ Post_{\mathcal{A}(K)}(S) = \emptyset \)

\(^b\)It can be surprising that neither \( \delta_3^- \) nor \( \delta_4^- \) appear in \( K_0 \). This constraint \( K_0 \) actually prevents \( G_2 \) from any change, as \( g_1 \) and \( CK \) are never both set to 1; therefore, \( g_2 \) always remains set to 1, and the delay of \( G_2 \) does not have any influence on the system for the considered environment.

\(^c\)Our instantiation \( \pi_0 \) was actually chosen in order to satisfy \( Z \).
all the properties and Theorem 22 of Sect. 3.3 still hold, and can be proved similarly.

We consider an “And–Or” circuit described in [7] and depicted on Fig. 4.1 left. It is composed of 2 gates (one “And” gate and one “Or” gate) which are interconnected in a cyclic way. Each rising (resp. falling) edge of signal $a$, is denoted by $a^\uparrow$ (resp. $a^\downarrow$), and similarly for $b, t, x$. The delay between the rising and the falling edge of $a^\uparrow$ (resp. $a^\downarrow$) and $a^\downarrow$ (resp. $a^\uparrow$) is in $[\delta_{a^\downarrow}^-, \delta_{a^\uparrow}^+]$ (resp. $[\delta_{a^\uparrow}^-, \delta_{a^\downarrow}^+]$), and similarly for $b$. The traversal of the gate Or takes also a delay in $[\delta_{\text{Or}}^-, \delta_{\text{Or}}^+]$, and likewise for gate And. There are 12 timing parameters. We consider the following instantiation $\pi_0$ of the parameters:

\[
\begin{align*}
\delta_{a^\uparrow}^- & = 13 & \delta_{a^\downarrow}^+ & = 14 & \delta_{a^\downarrow}^- & = 16 & \delta_{a^\uparrow}^+ & = 18 & \delta_{b^\uparrow}^- & = 7 & \delta_{b^\downarrow}^+ & = 8 \\
\delta_{a^\downarrow}^- & = 19 & \delta_{a^\uparrow}^+ & = 20 & \delta_{\text{And}}^- & = 3 & \delta_{\text{And}}^+ & = 4 & \delta_{\text{Or}}^- & = 1 & \delta_{\text{Or}}^+ & = 2 
\end{align*}
\]

We consider an environment starting at location $q_0$ with $a = b = x = t = 1$, and the following repeated cycle of alternating rising and falling edges of $a$ and
b: \(b^1, a^1, b^1, a^1\). Under this environment and the reference valuation \(\pi_0\), the set of traces is given on Fig. 4.1 right under the compact form of a reachability graph.

Applying algorithm InverseMethod\(^\prime\) (implemented in Imitator), the following constraint is computed (in [7], the generated constraint is not explicitly given):

\[
0 < \delta_{a_i}^- \land 0 < \delta_{And}^- \land 0 < \delta_{Or}^- \land \delta_{And}^+ + \delta_{bi}^+ < \delta_{a_i}^- \land \delta_{a_i}^+ + \delta_{bi}^+ < \delta_{a_i}^- \land \delta_{bi}^- + \delta_{bi}^- < \delta_{bi}^+ + \delta_{a_i}^+ \land \delta_{Or}^- + \delta_{And}^- < \delta_{bi}^+.
\]

The set of traces is guaranteed to be the same as the one depicted on Fig. 4.1.

4.2. Second Extension

In order to make the method terminate more often, we relax the termination condition in InverseMethod\(^\prime\) by replacing the expression IF \(\forall s \in Post_{A(K)}(S), \exists s' \in S: s = s'\) with the more general expression IF \(\forall s \in Post_{A(K)}(S), \exists s' \in S: s \subseteq s'\).

Note that this termination test actually corresponds to the subsumption test used in HyTech. Let InverseMethod\(^\prime\) denote this modified algorithm.

Suppose that InverseMethod\(^\prime\)\((A, \pi_0)\) terminates with output \(K_0\). Let \(K''\) (resp. \(S''\)) be the current constraint on the parameters (resp. the current set of reachable states) when the algorithm InverseMethod\(^\prime\) terminates. We have \(S'' = Post_{A(K'' \{ \{s_0\} \}}^\prime(\exists X : C)\) and \(K_0'' = \bigcap_{(q, C) \in S''} (\exists X : C)\). However, a state \((q, C)\) reached by a symbolic run of \(A(K'')\) is now in general strictly included into some state previously generated. Therefore it may lose the \(\pi_0\) -compatibility property. Thus, the counterparts of Prop. 17 and 19 do not hold any longer. Nevertheless, it is easy to see that the sets of locations reached by symbolic runs are identical to those reached by concrete runs. Let \(Loc^* (A[\pi])\) denote the set of reachable locations of \(A[\pi]\), i.e., \(\{q \mid \exists C : (q, C) \in Post_{A[\pi]}^*(\{s_0\})\}\). We have:

**Theorem 25.** Suppose that InverseMethod\(^\prime\)\((A, \pi_0)\) terminates with output \(K_0''\). Then, we have: (1) \(\pi_0 \models K_0''\), and (2) for all \(\pi \models K_0''\), \(Loc^* (A[\pi]) = Loc^* (A[\pi_0])\).

Note that Theorem 25 still holds with \(K''\) instead of \(K_0''\), i.e., \(\pi_0 \models K''\), and \(Loc^* (A[\pi]) = Loc^* (A[\pi_0])\), for any \(\pi \models K''\).

**Remark.** The second part of Theorem 25 is interesting when \(A[\pi_0]\) is known to avoid a given bad location because, in this case, \(A[\pi]\) is also guaranteed to avoid this bad location, for any \(\pi \models K''\). This is the case of the SIMOP case study [3].

5. Experiments

The algorithm InverseMethod, as well as its two variants, has been implemented under the form of a program named Imitator, which stands for Inverse Method for Inferring Time Abstract Behavior. This program, containing about 1500 lines of code, is written in Python and calls the parametric model checker HyTech [13] in order to compute the Post operation. See [4] for details.

A table of results is presented below. We give from left to right the name of the example, the number of PTAs composing the global system \(A\), the lower and upper
bounds on the number of locations per PTA, the number of clocks and parameters of $\mathcal{A}$, of iterations of the algorithm, of reachable symbolic states, of inequalities of $K_0$ (put under a simplified form), and the computation time. The fully detailed experiments are available in [3].

| Example  | PTAs | loc. per PTA | # clocks | # param. | # iter. | $|Post^*|$ | $K_0$ | CPU time |
|----------|------|--------------|----------|----------|---------|---------|--------|----------|
| Flip-flop [8] | 5 | [4, 16] | 5 | 12 | 8 | 11 | 6 | 2 s |
| And–Or [7] | 3 | [4, 8] | 4 | 14 | 13 | 14 | 13 | 3 s |
| RCP [20] | 5 | [6, 11] | 6 | 5 | 18 | 154 | 2 | 70 s |
| CSMA/CD [17, 23] | 3 | [6, 7] | 4 | 3 | 21 | 294 | 3 | 108 s |
| SIMOP [3] | 5 | [6, 16] | 9 | 16 | 51 | 848 | 7 | 419 min |

We used Algorithm $InverseMethod$ for the flip-flop, CSMA/CD, RCP\textsuperscript{d}, and SPSMALL examples. We used the first extension $InverseMethod'$ for the And–Or example, and the second extension $InverseMethod''$ for the SIMOP case study.

### 6. Extension: Incremental Method

We presented in Sect. 3 how to synthesize a constraint from a given instantiation of the parameters. We now aim at widening this constraint in order to cover a predefined zone $Z$. The method we now present can be summarized as follows: we pick up an instantiation $\pi_1$ in $Z$, we find a constraint with $InverseMethod$, and we iterate this operation until $Z$ is completely covered.

Considering again our flip-flop example described in Sect. 2.4, we aim at widening the constraint $K_0$ found in Sect. 3.5 from the instantiation $\pi_0$. Recall that $\pi_0$ satisfies the constraint $Z$. Since $Z \not\subseteq K_0$, there exists a different instantiation of the parameters satisfying constraint $Z$, and not $K_0$. For example, consider the instantiation $\pi_1$ defined as follows (the differences with $\pi_0$ are in bold):

- $T_{\text{HI}} = 23$
- $T_{\text{LO}} = 15$
- $T_{\text{setup}} = 10$
- $T_{\text{hold}} = 17$
- $\delta_1^- = 7$
- $\delta_1^+ = 7$
- $\delta_2^- = 5$
- $\delta_2^+ = 6$
- $\delta_3^- = 8$
- $\delta_3^+ = 10$
- $\delta_4^- = 3$
- $\delta_4^+ = 5$

The set of traces of the system under $\pi_1$ and the environment considered in Sect. 2.4 is depicted in Fig. 6, under the form of an oriented graph. Note that it is a subgraph of the set of traces of the system under $\pi_0$ (Fig. 3). Applied to the NPTA modeling the flip-flop circuit, our program generates the following constraint $K_1$:

$$T_{\text{setup}} < T_{\text{LO}} \land T_{\text{hold}} < T_{\text{HI}} \land \delta_1^- + \delta_4^- < T_{\text{hold}} \land \delta_1^+ + \delta_4^+ < T_{\text{setup}}$$

It is easy to see now that $Z \not\subseteq K_0 \cup K_1$. In other terms, our union of constraints $K_0 \cup K_1$ represents a strictly bigger set of parameter valuations than $Z$. Note that, although $Z \not\subseteq K_0 \cup K_1$, the sets of time-abstract behaviors under $Z$ and $K_0 \cup K_1$ are the same ($K_0 \cup K_1$ does not add any trace to $Z$).

\textsuperscript{d}We considered an acyclic model for CSMA/CD and RCP by bounding the maximal number of collisions of messages.
We now give this algorithm IIM (standing for Incremental Inverse Method) on Fig. 7. It outputs a disjunction \( \mathcal{D} \) of constraints \( K_0, K_1, \) etc. The notation \( \pi \not\models \mathcal{D} \) means \( \pi \not\models K_i \), for all \( i = 0, 1, \ldots \).

**7. Final Remarks**

We presented an algorithm \texttt{InverseMethod} which synthesizes a constraint \( K_0 \) under which the studied PTA yields the same set of traces as under a reference parameter valuation \( \pi_0 \). Note that, although the final constraint \( K_0 \) induces a behavioral property of the system related to traces, only states (and not traces) are manipulated by the algorithm. The method is guaranteed to terminate in the acyclic case. For the cyclic case, we adapt the method in order to improve termination at the price of getting an overapproximation of the set of traces.

Our method is complementary to the CEGAR-based methods that assume given a set of bad states to be avoided. We showed how these two kinds of methods can be combined together, using algorithm IIM.

It can be shown that \texttt{InverseMethod} is (in general) non-confluent, i.e., several applications of \texttt{InverseMethod} to the same instance \( \pi_0 \) may lead to a different \( K_0 \). It follows from this remark that the generated constraint \( K_0 \) is not maximal, i.e., there may exist \( \pi \not\models K_0 \) such that the traces of \( A[\pi_0] \) and the traces of \( A[\pi] \) are identical. In practice, we observe on all the experiments of Sect. 5 a confluent behavior of the algorithm. However, the constraint generated is not always maximal. It would be interesting to evaluate how large is the constraint generated by \texttt{InverseMethod}.

**Acknowledgment**

We are grateful to Laurent Doyen for a helpful discussion, and we thank Jeremy Sproston and the anonymous referees for helpful comments.
